

# Cryolithionite-Based Pseudocapacitive Electrode for Sustainable Lithium-ion Capacitors

Lukas Ladenstein<sup>+[a]</sup> Xuexue Pan<sup>+[b]</sup> Hung Q. Nguyen,<sup>[c]</sup> Daniel Knez,<sup>[d]</sup> Martin Philipp,<sup>[a]</sup> Gerald Kothleitner,<sup>[d]</sup> Günther J. Redhammer,<sup>[e]</sup> Qamar Abbas,<sup>\*[a, f]</sup> and Daniel Rettenwander<sup>\*[a, c]</sup>

Lithium-ion insertion/deinsertion in anode at slow rates limits the power performance of energy storage devices. Here, a new pseudocapacitive electrode with high reversible capacity during cycling has been proposed for a lithium-ion capacitor. The lithium-fluoride garnet, namely  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$ , is obtained via precipitation from an aqueous solution at room temperature using abundant materials and exhibits a high discharge capacity of  $746 \text{ mAh g}^{-1}$ . After the first charging cycle, the energy is stored via fast pseudocapacitive faradaic reactions

which are facilitated by the nanocrystalline transport pathways with no structural modification to the electrode. The high stability window of F-garnet allows extracting cell voltages of 2.2–3.2 V in a lithium-ion capacitor where it is coupled with a porous carbon-based positive electrode, with a high energy efficiency of 93% maintained for 10000 charge/discharge cycles. This study opens a new research direction concerning pseudocapacitive anode materials for enhancing power performance and even replacing the traditional battery-like anode materials.

## 1. Introduction

Metal-ion capacitors (MICs) are suitable for applications where high energy density along with high power is needed, e.g., regenerative braking, stop/start systems, or peak-power shaving.<sup>[1–4]</sup> In such applications, a high-power performance is desirable to relieve the coupled battery system from stress during peak power demand and enhance its operational life.<sup>[5,6]</sup> Therefore, new materials with fast charge/discharge character-

istics are needed to improve the rates at which energy is stored and delivered. There is a growing need in the energy storage market to develop devices with high power and improved cycle life in order to lower the cost per Wh as well as the overall cost per cycle.<sup>[7,8]</sup> A prime example of MICs is the lithium-ion capacitor (LIC) that fills the energy gap between lithium-ion batteries (LIBs) and traditional electric double-layer capacitors (EDLCs). In contrast to  $150\text{--}200 \text{ Wh kg}^{-1}$  for LIBs, and  $3\text{--}7 \text{ Wh kg}^{-1}$  for EDLCs, the LICs display  $50\text{--}60 \text{ Wh kg}^{-1}$  at high C-rates and cycle-life up to 0.5 million cycles.<sup>[9–13]</sup> Nevertheless, their power density is much lower than the EDLCs and the main bottleneck is the low efficiency of battery-like electrodes or anodes. Since the second electrode in these devices is made from high surface area carbon, the rate of charge storage at this electrode is high due to the physical charging of electric double-layer (EDL).

Currently, the generally accepted structure of LICs is a battery-type anode with a constant narrow potential range and a capacitor-type positive electrode with a broad linear potential range.<sup>[14–17]</sup> Devices with this structure have clear constraints in the charging and discharging process. The lowest potential of the positive electrode potential should be greater than 2.2 V vs.  $\text{Li}/\text{Li}^+$  to avoid the formation of solid electrolyte interface (SEI) film on the surface of the positive electrode active materials (e.g., activated carbon).<sup>[18–20]</sup> Moreover, the highest potential of the cathode material should be lower than the oxidation potential of the electrolyte (e.g., 4.3 V vs.  $\text{Li}/\text{Li}^+$ ).<sup>[21]</sup> In terms of the negative electrode, its main problem is that the lithium ions are consumed to form the SEI film and the  $\text{Li}^+$  inserted into the structure of the anodic host during the 1<sup>st</sup> discharge.<sup>[22,23]</sup> Until now, the two most popular approaches utilize additional metal lithium electrodes and sacrificial materials (also called lithium-containing additives) mixed with activated carbon in the positive electrode.<sup>[24–26]</sup> When the irreversible capacity of the negative electrode material is large or the coulombic efficiency

is low, the prelithiation process is satisfied because the metal lithium electrode can provide a large number of lithium ions. However, this process requires the two-step assembly of LICs, which increases the expenditure and reduces the possibility to use this strategy in a commercial way. On the contrary, sacrificial materials are suitable for anode materials with small irreversible capacity or high coulombic efficiency.<sup>[24,27]</sup> The advantage of using sacrificial materials is that the device only needs to be assembled once, reducing the cost of additional steps. However, because the mass of the sacrificial material is calculated based on the mass and the first discharge capacity of the anode material, and the practical capacity of the sacrificial material to remove lithium ions, the added sacrificial material in the positive electrode will significantly increase the mass of the positive electrode, thereby raising the thickness of the positive electrode to enhance the internal resistance of the positive electrode. In addition, after prelithiation, the oxidation products of the sacrificial material can stay inside the device and may negatively affect the performance of the device.<sup>[28]</sup> A second very important issue for battery-type anodes is the narrow potential range in which the charge-discharge curve of the anode material should be stable even at high current densities. Therefore, the voltage range of the device can be determined based on the above requirements. The last significant issue is that in the study of LICs, it is very important to balance the mass of the positive electrode due to the different kinetic processes of the positive and negative electrodes.<sup>[21,29,30]</sup> It can affect the cycle life and energy density of the device. For junior researchers to study LICs, it is recommended to use positive and negative electrode active materials with a mass ratio of 1:1.<sup>[31–33]</sup>

Recently, Glushenkov et al.<sup>[16]</sup> proposed a new and interesting structure of LICs (upside-down cells), which consists of a battery-type cathode with a constant narrow potential range and a capacitive negative electrode with a broad linear potential range. This device structure may eliminate prelithiation techniques because the cathode is a lithium-containing battery-type material. Indeed, we can assume that during the cycling of LICs, the huge available area of the activated carbon below 1.6 V vs. Li/Li<sup>+</sup> accelerates the decomposition of the electrolyte, thereby forming a SEI film on the surface of the active material, plugging the micropores, increasing the resistance and allowing the generation of gases, with severe consequences on the degradation of the electrode and the entire cell.<sup>[34]</sup> However, either classical or upside-down structure of LICs uses battery-type materials, which often experience volume expansion during cycling, resulting in poor cycle life of devices. Pseudocapacitive materials react with lithium ions and exhibit redox reactions into the near-surface (e.g., RuO<sub>2</sub>, MnO<sub>2</sub>) or their interlayer spacing (e.g., MoS<sub>2</sub>, WS<sub>2</sub>, Ti<sub>3</sub>C<sub>2</sub>), which can maintain an intact structure after long cycles.<sup>[9,35]</sup> Based on the two constructions of existing LICs and the properties of pseudocapacitive materials, we propose an additional concept of LICs. In this device, there is a pseudocapacitive material negative electrode with a broad linear potential range and a capacitive material positive electrode with a constant narrow potential range.

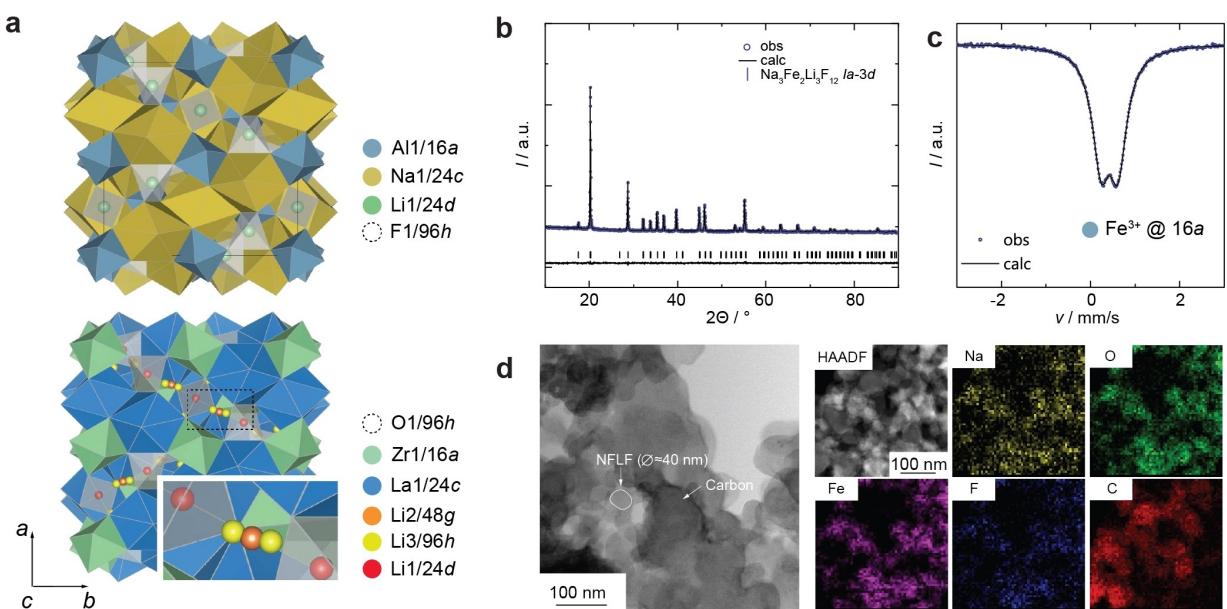

Cryolithionite, with the formula Na<sub>3</sub>Al<sub>2</sub>Li<sub>3</sub>F<sub>12</sub>, is a unique natural mineral of the fluoride garnet group that occurs in hydrothermal deposits associated with minerals of other alumino-fluorides (e.g., Ivigtut, Greenland).<sup>[36,37]</sup> In the last several decades, some mineralogical and crystallographic efforts were undertaken to substitute Al in Na<sub>3</sub>Al<sub>2</sub>Li<sub>3</sub>F<sub>12</sub> by third-row transition metals, such as Fe, Co, Ni, Ti, V, Cr, as well as other elements, such as Sc, Ga, In, and Rh.<sup>[38–41]</sup> Surprisingly, Cryolithionite has not received any attention for energy storage applications despite belonging to the garnet group, which is known to be one of the most promising groups of materials for solid electrolytes, e.g., La<sub>3</sub>Zr<sub>2</sub>Li<sub>7</sub>O<sub>12</sub>, used in Li-ion batteries today (see Figure 1a).<sup>[42,43]</sup> Although Li-oxide garnets are well known as solid electrolytes, they can also be used as electrode material if a redox active center is present as Goodenough and coworkers demonstrated.<sup>[44]</sup> They were able to reversibly insert 4 Li<sup>+</sup> per formula unit (Li<sub>3</sub>Nd<sub>3</sub>W<sup>6+</sup><sub>2</sub>O<sub>12</sub> + 4Li<sup>+</sup> + 2e<sup>-</sup> ⇌ Li<sub>7</sub>Nd<sub>3</sub>W<sup>4+</sup><sub>2</sub>O<sub>12</sub>) into the oxide-garnet lattice with an initial capacity of 105 mAh g<sup>-1</sup>. In the case for Li-fluoride garnets (Na<sub>3</sub>M<sub>2</sub>Li<sub>3</sub>F<sub>12</sub>, with M=Ti, V, Cr, Mn, Fe, Co, Ni, and Cu) theoretical gravimetric and volumetric capacities of up to 260 mAh g<sup>-1</sup> and 745 mAh cm<sup>-3</sup> could be potentially achieved, respectively. A further advantage of cryolithionites is the possibility to synthesize the material at room temperature<sup>[45]</sup> – this makes its preparation low cost, which is particularly important to drop the price per kWh. Cryolithionite is a fluoride that tends to form strong Li–F bonds, which is a disadvantage in terms of Li mobility, hence, Li insertion. However, this could become an attractive material for energy storage by inducing pseudocapacitive characteristics due to the Fe<sup>2+</sup>/Fe<sup>3+</sup> redox activity present in the crystal lattice.

Therefore, we synthesized phase pure nano-crystalline Na<sub>3</sub>Fe<sub>2</sub>Li<sub>3</sub>F<sub>12</sub> (NFLF) powder at room temperature by precipitation from an aqueous solution and thoroughly characterized it by using a wide spectrum of characterization techniques. Indeed, we found that NFLF displays pseudocapacitive properties after first lithium insertion, which fits well to the fast EDL charging of high surface area nanoporous carbon electrodes. Thus, the designed LIC displays high cycle life and rate performance that makes it adaptable for a range of applications to quickly harvest and deliver energy. Moreover, the LIC device assembled with NFLF and activated carbon operates between 2.2–3.2 V, displays a constant capacitance of ca. 26 Fg<sup>-1</sup> and high energy efficiency during 10000 galvanostatic charge/discharge cycles.

## 2. Experimental Section

### 2.1. Synthesis

Na<sub>3</sub>Fe<sub>2</sub>Li<sub>3</sub>F<sub>12</sub> was synthesized using 10 mL of NaOH, and stoichiometric amounts of LiOH and NaFeO<sub>2</sub>. During stirring a precipitation was formed, which was then dissolved by adding HCl until a pH value of 2 was achieved. The solution 10 mL of 5% HF (1:10 in methanol) was added. The fluoride garnet then precipitated overnight and was purified by washing with methanol 3 times.

**Figure 1.** Crystal chemistry and Morphology. **a**  $\text{Na}_3\text{Al}_2\text{Li}_3\text{F}_{12}$  and  $\text{La}_3\text{Zr}_2\text{Li}_2\text{O}_{12}$  garnets (Space group:  $\text{I}\bar{a}-3\text{d}$ ).<sup>[5,6]</sup> In Li-fluoride garnet structure the F- are located at the general crystallographic position 96 h (not shown), which forms a F- framework with interstices occupied by  $\text{Na}^+$  at the eight-fold coordinated position 24c (A-site), by  $\text{Al}^{3+}$  (or  $\text{Fe}^{3+}$  in case of  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$ ) at the six-fold coordinated position 16a (B-site), and by  $\text{Li}^+$  at the four-fold coordinated 24d position (C-site). The high Li-ion conductivity of Li-oxide garnets is caused by the occupation of interstices within the oxide framework (six-fold coordinated 48 g and 96 h position) with extra  $\text{Li}^+$  forming a 3-D pathway providing high Li-ion diffusivity. **b** The observed (obs), calculated (calc), and difference patterns (obs-calc) for the Rietveld refinement from powder X-ray diffraction of  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$ . The short vertical lines below the profiles mark the reflection positions of all possible Bragg reflections of this phase. **c** Mössbauer spectrum of  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$  shows doublet, which could be assigned to  $\text{Fe}^{3+}$  at the 16a site. **d** STEM annular bright-field (ABF) image of a composite electrode containing  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$  particles. The image series depicts a STEM HAADF image of a representative area of the electrode and corresponding EDS elemental maps.

## 2.2. X-ray Diffraction

To check if the synthesis was successful X-ray powder diffraction measurements were carried out using a Bruker D8 Advance diffractometer operating with  $\text{CuK}\alpha$  radiation. Data were collected at angles  $2\theta$  ranging from  $10^\circ$  to  $100^\circ$ . X-ray powder diffraction data were refined using the Fullprof-suite of programs

10 MHz. To avoid any influence of oxygen or water, the measurements in the sample cell (BDS 1200, Novocontrol) were controlled by a QUATRO cryosystem (Novocontrol) with a stream of freshly evaporated  $\text{N}_2$  gas. Polarization measurements were conducted at  $20^\circ\text{C}$  in a climate chamber at a potential of 100 mV. To avoid any influence of moisture during the measurement, the pellets were assembled in Swagelok-cells under Ar atmosphere in the glove box (MBraun labmaster pro sp,  $< 0.1 \text{ ppm O}_2$ ,  $< 0.1 \text{ ppm H}_2\text{O}$ ).

## 2.3. Mössbauer Spectroscopy

The Fe oxidation states and possible cationic distributions were determined by  $^{57}\text{Fe}$  Mössbauer spectroscopy using an apparatus (Halder Electronics, Germany) in horizontal arrangement ( $^{57}\text{Fe}$  Co/Rh single-line thin source, constant acceleration model with symmetric triangular velocity shape, a multi-channel analyzer with 1024 channels, regular velocity calibration against metallic Fe). Data evaluation was performed using the program Recoil allowing the use of a full static hyperfine interaction Hamiltonian analysis with Lorentzian-shaped doublets, but also a Voigt-based hyperfine parameter distribution analysis.

## 2.4. Electrochemical Analysis

To investigate the ion conduction of  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$  (NFLF), Electrochemical Impedance Spectroscopy (EIS) and polarization experiments were conducted. Therefore, dried NFLF powder was uniaxially pressed into pellets (diameter  $d = 5 \text{ mm}$ , thickness  $h \sim 1 \text{ mm}$ ) under a force of 0.5 kN. Au blocking electrodes with a thickness of 50 nm were applied on both sides of the pellet with a Leica EM SCD 050 sputter device. EIS was recorded between  $-60^\circ\text{C}$  to  $240^\circ\text{C}$  in  $10^\circ\text{C}$  steps using a Novocontrol Concept 80 broadband dielectric spectrometer, covering a frequency range from 10 mHz to

## 2.5. Cell Assembling and Electrochemical Testing

The electrode was prepared by 140 mg  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$  mixed with 50 mg Super C65, 10 mg Knyar 761 (PVDF) and 0.95 ml N-Methyl-2-pyrrolidone. The obtained slurry was cast on a Cu-foil with a thickness of  $100 \mu\text{m}$  and dried at  $60^\circ\text{C}$  for 12 h in a climate chamber. 10 mm diameter electrodes were stamped out of the copper foil and were dried again under reduced pressure of (10–4 mbar) for 12 h. Free-standing carbon electrodes were prepared by mixing 90 wt% of the microporous YP80F carbon (from Kuraray) with 5 wt% carbon black (C65 from Imerys), and 5 wt% of polytetrafluoroethylene (60% dispersion in water from 3M Chemicals) in isopropanol. The mixture was stirred at  $78^\circ\text{C}$ , and a dough was obtained, pressed and rolled on a glass plate into a thin sheet. The electrode sheet was dried at  $120^\circ\text{C}$  and calendared to achieve a final thickness of about  $150 \mu\text{m}$ , from which the disc electrodes were punched out. The electrolyte was  $1 \text{ mol L}^{-1}$   $\text{LiPF}_6$  (origin, grade) in EC:DMC solvent (origin, grade) soaked in a GF/A glassy fiber that acts as a separator. The pre-lithiation of F-garnet was performed in a separate cell versus metallic lithium as counter and reference electrodes. For three-electrode cell measurements and prelithiation of NFLF electrode, Swagelok-type cells with a Li/Li<sup>+</sup> reference electrode were assembled and lithium intercalation was carried out at a slow scan rate of  $0.05 \text{ mV s}^{-1}$ . Cyclic voltammetry at

a scan rate from  $0.05 \text{ mVs}^{-1}$  up to  $50 \text{ mVs}^{-1}$  and galvanostatic charge/discharge measurements were carried out up to  $100 \text{ mA g}^{-1}$ . The prelithiated F-garnet (negative electrode) and activated carbon (positive electrode) were coupled in a separate Swagelok-type cell where electrodes were pasted onto the stainless steel cylinders acting as current collectors. The hybrid LICs were assembled by using about  $150 \mu\text{L}$  electrolyte and the working to counter electrode mass ratio of 1:1 was used. The specific current and capacitance values are expressed per total mass of electrodes including the binder and conductivity enhancer. The resulting rate capability, cycle life and the self-discharge measurements were carried out at maximum reachable voltage. The LIC cell was charged at the maximum voltage of 3.2 V for 4 hours before the open circuit during self-discharge measurements. Electrochemical measurements on supercapacitor cells were performed with a VMP3 multichannel potentiostat/galvanostat (Bio-Logic Instruments). The energy density  $E$  ( $\text{Wh kg}^{-1}$ ) and power density  $P$  ( $\text{W kg}^{-1}$ ) of the capacitors were calculated by

$$E = 3.6I_m \int U dt \quad (1)$$

$$P = \frac{E}{3600 t} \quad (2)$$

The coulombic efficiency of the capacitor (C.E) is calculated by

$$C.E = (t_{\text{discharge}} / t_{\text{charge}}) \cdot 100. \quad (3)$$

where  $t_{\text{discharge}}$  is the time of discharge and  $t_{\text{charge}}$  the time of charge in a given potential range.

## 2.6. TEM

TEM sample preparation was performed via focused ion beam (FIB) milling with Ga ions using a FIB/SEM Dual Beam Microscope FEI NOVA 200. The lift out and initial milling step was performed with 30 kV ions and the final milling step was done at 5 kV. The resulting lamellae were mounted onto an Omniprobe copper-based lift-out grid and directly transferred to the microscope. STEM observations were carried out by a probe corrected FEI TITAN3 G2 microscope operated at 300 kV in scanning mode. The microscope is equipped with a SuperX four-quadrant EDX detector. Selected area electron diffraction (SAED) experiments were performed using a FEI Tecnai F20 microscope, operated at 200 kV.

## 2.7. X-ray Photoelectron Spectroscopy

To study the oxidation state and bonding structure of elements within the as-synthesized materials and electrodes, X-ray photoelectron spectroscopy (XPS) analyses were acquired with a Kratos Axis Ultra Spectrometer (Kratos Analytical Ltd) using a monochromatic Al  $K\alpha$  source (10 mA, 10 kV). The chamber were maintained  $5 \times 10^{-9}$  Torr pressure during the measurements. The spectra were collected using an analysis area of  $\sim 300 \mu\text{m} \times 700 \mu\text{m}$  with 20 eV pass energy. The Kratos charge neutralizer system was utilized in all measurements and all spectra were shifted by following the adventitious carbon C–C peak at 284.8 eV in C 1s spectrum.

## 3. Results and Discussion

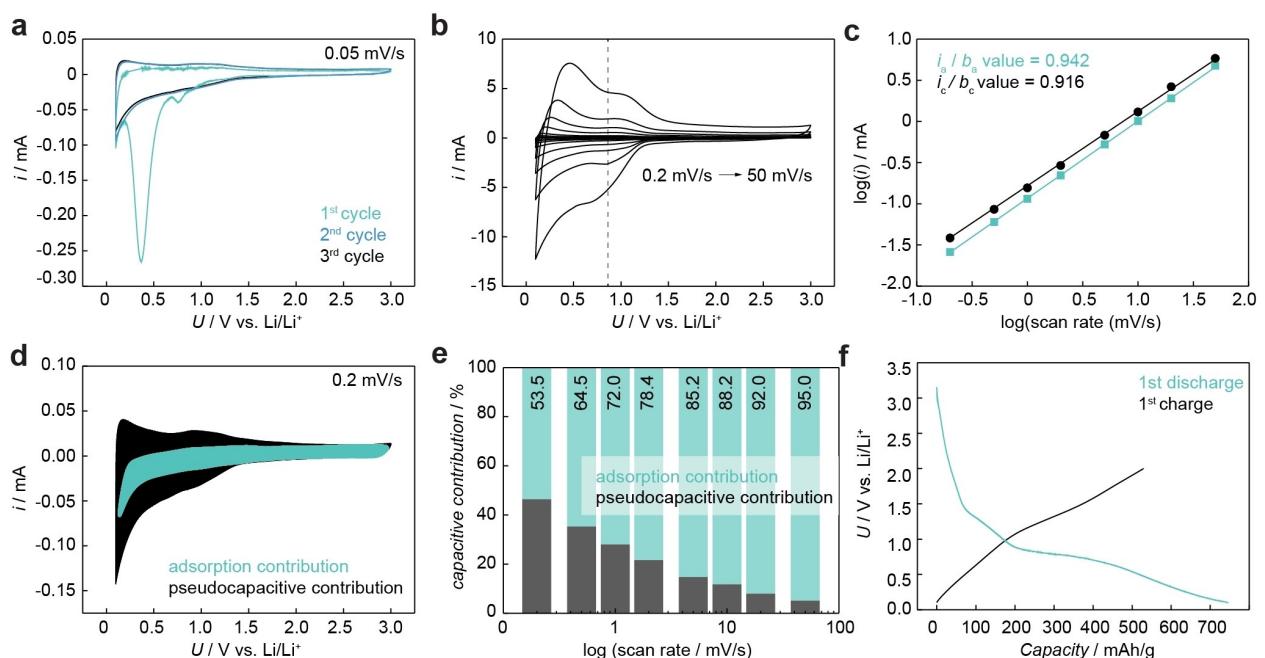

### 3.1. The (Crystal) Chemistry

NFLF was prepared via precipitation from an aqueous solution (see Figure S1 and experimental details). A fine brownish powder was obtained. The corresponding X-ray diffraction pattern of NFLF is shown in Figure 1b.

The data can be indexed on basis of the standard garnet structure in the space group in close relation to the structure of cryolithionite  $\text{Na}_3\text{Al}_2\text{Li}_3\text{F}_{12}$ <sup>[37]</sup> and synthetic  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$ ,<sup>[47]</sup> no indications were found for a symmetry reduction caused by H–Li exchange as a result from the synthesis in an aqueous solution as known for, e.g., Li-oxide garnets.<sup>[48]</sup> Observed lattice parameters are  $a=12.4118(2) \text{ \AA}$  and are of similar size to those of the material obtained by Takeda, et al.,<sup>[45]</sup> also by precipitation from an aqueous solution with  $a=12.407(2) \text{ \AA}$ . In the structure of  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$ , sodium occupies the 24c site with an eightfold fluor atom coordination, the octahedrally coordinated 16a site hosts iron, while Li resides on the 24d position and is in tetrahedral coordination. Based on the Rietveld refinements (Figure 1b) on the powder diffraction data, the 24c and the 16a site appear to be fully occupied, however, a slight Li deficit might be present at the 24d site, due to the low scattering contrast of Li, but this cannot be fully validated (see SI for more details).  $^{57}\text{Fe}$  Mössbauer spectroscopy in Figure 1c proved the presence of solely ferric iron in octahedral coordination, no  $\text{Fe}^{2+}$  is present, nor is there any hint for  $\text{Fe}^{3+}$  on other sites. The slight line broadening in the low and high-velocity wings of the resonance absorption lines is indicative for a distribution of local distortion environments around iron ions. This is related to the high sensitivity of the electrical field gradient even for small changes in the anionic coordination associated with, e.g., different next-nearest neighbour chemistry. Due to the nano-scale nature of NFLF particles (ca. 40 nm with an uniform distribution of all elements; see Figure 1d) surface terminated iron with distorted coordination sphere gets a prominent resulting in a broadening of the resonance absorption lines (see SI for details). Such structural merit may facilitate the lithium insertion/deinsertion that fundamentally contributes to pseudo-capacitive energy storage of the anode.

### 3.2. The Electrochemical Performance

The cyclic voltammogram of the NFLF electrode recorded at a scan rate of  $0.05 \text{ mVs}^{-1}$  down to a vertex potential of 0.1 V vs.  $\text{Li}/\text{Li}^+$  (obtained with a three-electrode setup) is shown in Figure 2a. Three reduction peaks can be observed, whereby the first peak at 0.98 V vs.  $\text{Li}/\text{Li}^+$  can be assigned to the SEI formation, the second and third prominent peaks at 0.8 V and 0.39 V vs.  $\text{Li}/\text{Li}^+$  are associated with lithium insertion of NFLF structure. However, these reactions may partially change the morphology (i.e., amorphization) of NFLF. The overlap of the 2nd and 3rd cycles reveals the good reversibility of Li storage after the 1st cycle, suggesting that a stable SEI film is formed during the initial cycle. In Figure 2b, even at high scan rates, the

**Figure 2.** Electrochemical performance of  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$ . **a** Initial cyclic voltammograms (scan rate = 0.05 mV/s) during the first lithium insertion in  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$ , which was repeated for 3 CVs down to a vertex potential of 0.1 V vs.  $\text{Li}/\text{Li}^+$ . **b** CV curves of  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$  at different scan rates from 0.2 mV/s to 50 mV/s. **c** determination of the  $b$  value using the relationship between anodic or cathodic currents and scan rates at the potential of 0.8 V vs.  $\text{Li}/\text{Li}^+$ . **d** separation of the adsorption contribution and pseudocapacitive contribution at 0.2 mV/s. **e** contribution ratio of the adsorption contribution and pseudocapacitive contribution vs. scan rate. **f** the first galvanostatic discharge-charge of  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$  at 25 mA/g.

peaks related to lithium insertion/deinsertion maintain their original shape and become broader compared to peaks at low scan rates. The cathodic peaks become steeper due to diffusion-related polarization, and the anodic peaks shift to higher potentials with increasing scan rates. The storage mechanism of lithium for NFLF is firstly investigated by the Kinetic calculation. The CV data are collected at different scan rates (Figure 2b), from which the ratio of the capacitive contribution could be obtained. Based on the equation of  $\log(i) = b \log(v) + \log(a)$  between the current ( $i$ ) and scan rate ( $v$ ), the value of  $b$  is determined by the slope of  $\log(i)$  and  $\log(v)$  curve, while the  $b$ -value close to 1.0 signifies that the electrochemical process is controlled by the capacitive response, whereas  $b$ -value close to 0.5 indicates the diffusion process is dominating.<sup>[49]</sup> The  $b$ -value from the anodic or cathodic current at 0.8 V vs.  $\text{Li}/\text{Li}^+$  is calculated to be 0.942 or 0.916 (Figure 2c), respectively. Interestingly, the  $b$  value is between 0.5 and 1, much close to 1, indicating that the capacitive effect may occupy the main parts of the charge storage behavior. In general, the capacitance process includes adsorption capacitance and pseudocapacitance.<sup>[35]</sup> Actually, materials with pseudocapacitive properties also participate in the diffusion process.<sup>[35]</sup> Thus, the detailed quantification of capacitive contribution is measured according to the Dunn's method<sup>[50]</sup> to acquire the actual ratio and the following equation  $i = k_1v + k_2v^{1/2}$ , where  $i$  represents the current value,  $k_1$  and  $k_2$  are the constant,  $v$  is the scan rate,  $k_1v$  and  $k_2v^{1/2}$  are the adsorption contribution and pseudocapacitive contribution, respectively. In the preliminary cycle, the adsorption capacitance contribution for a scan rate of 0.2 mV/s<sup>-1</sup> is 53.5% (see Figure 2d).

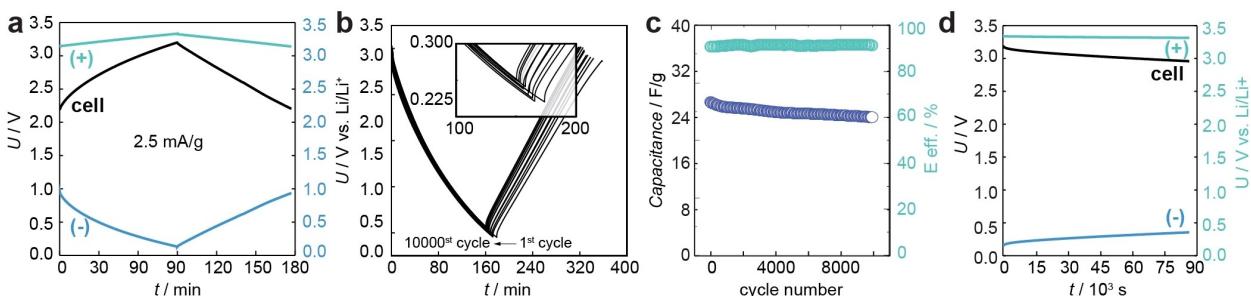

Furthermore, the adsorption contribution in Figure 2e is 64.5%, 72.0%, 78.4%, 85.2%, 88.2%, 92.0% or 94.8% with increasing scan rate (0.5, 1, 2, 5, 10, 20, 50 mV s<sup>-1</sup>), while the pseudocapacitive contribution is 35.5%, 28.0%, 21.6%, 14.8%, 11.8%, 8.0% or 5.2%. The ratio of capacitive contribution is quite limited by the adsorption process, indicating that the pseudocapacitive process plays a small part in the charge storage behaviors. The first galvanostatic charge-discharge curve in Figure 2f shows three plateaus at 1.1 V, 0.8 V and 0.2 V vs.  $\text{Li}/\text{Li}^+$  corresponding to the first CV cathodic process. The first discharge or charge capacity is 746 mAh g<sup>-1</sup> or 529 mAh g<sup>-1</sup>, respectively, which would result in an initial coulombic efficiency of 70.9%. A similar behavior has been reported for Fe-based anodes during lithium insertion.<sup>[51,52]</sup> The coulomb efficiency of 25 cycles is in the range of 82%, which can be seen from Figure S2. Specifically, after 1st cycle of SEI film formation, only the discharge time or discharge capacity from the 2nd cycle to the 4th cycle decreases slightly, while the discharge time or discharge capacity from the 5th cycle to the 25th cycle is almost unchanged. This clearly shows that no side reaction or irreversible faradaic deposition occurs after the successful formation of the SEI film.

### 3.3. The Electrochemical Evaluation in a Lithium-Ion Hybrid Capacitor

Since the low initial coulombic efficiency could consume a large number of lithium ions in LICs without prelithiation to form the SEI film and insertion material structure, we first used the metal

lithium electrode as the counter electrode to prelithiate the NFLF working electrode, and then the prelithiated NFLF electrode was removed from the pristine device and used as the anode together with cathode in the new device to assemble a LIC. The charge/discharge curves of a LIC assembled in  $1 \text{ mol L}^{-1}$  LiPF<sub>6</sub> in EC:DMC by coupling of lithium-inserted NFLF as anode and an activated porous carbon-based EDL electrode with the equal mass of NFLF and active carbon. The positive EDL electrode in Figure 3a displays symmetric charge/discharge curves in a narrow potential window of 3.4–3.5 V vs Li/Li<sup>+</sup>. Additionally, the minimum potential of the positive electrode is 2.2 V vs. Li/Li<sup>+</sup>, preventing any possible SEI formation on the AC surface,<sup>[18–21]</sup> while the maximum potential of the latter electrode is below the electrolyte oxidation limit of 4.3 V vs. Li/Li<sup>+</sup>.<sup>[21]</sup> The narrow potential window of the EDL electrode compared to the pseudocapacitive electrode (enlarged potential window of 0.1 to 1.0 V vs. Li/Li<sup>+</sup>) indicates the high capacity and charge storage capability. Moreover, the minimum potential of the negative electrode is higher than 0 V vs. Li/Li<sup>+</sup> to avoid the lithium plating.<sup>[53]</sup> Nevertheless, a relatively larger potential window for the pseudocapacitive electrode indicates a lower capacity compared to the carbon electrode at  $2.5 \text{ mA g}^{-1}$  (the specific current is based on the total mass of NFLF and carbon electrodes). The cell voltage shown in Figure 3a indicates an overall symmetric charge/discharge behavior of the LIC confirming the contribution from both electrodes and verifying the pseudocapacitance and EDL capacitance for anode and cathode, respectively, which is the structure we proposed in the introduction. To demonstrate the advantages of our proposed LICs, a series of electrochemical properties will be tested and compared to the literature. An energy density of  $41 \text{ Wh kg}^{-1}$  at a power density of  $0.61 \text{ kW kg}^{-1}$  has been estimated for the hybrid supercapacitor. Despite the gravimetric capacitance and energy values calculated per total mass of electrodes including the binder and conductivity additive, they are still comparable to the traditional Li-ion cells using a battery-like negative electrode.<sup>[54]</sup> The LIC was cycled between 3.2–2.2 V at a high specific current of  $50 \text{ mA g}^{-1}$  for 10000 galvanostatic charge/discharge cycles. During the cycling period, galvanostatic charge-discharge curves were collected

after every 1000 cycles in Figure 3b and charge-discharge time decreases slightly during cycling, where a small yet gradual decrease of capacitance can be seen and the energy efficiency remains at the level of 91% (Figure 3c). This decrease could be due to the interactions on the electrode surface where faradaic reactions occur, and these reversible reactions might be affected by electrolyte depletion or structural changes in the electrode over longer cycling periods (see below). Nevertheless, the symmetric charge/discharge curve after 10000 cycles and nearly constant capacitance of  $26 \text{ F g}^{-1}$  (per total mass of electrodes) during the cycling period indicates the stability, efficiency, and reversibility of faradaic processes. Another indication of LIC stable performance is shown by the self-discharge behavior in Figure 3d, where the overall cell voltage decreases by only  $\Delta U = 0.16 \text{ V}$  after an open circuit at 3.2 V for 24 h. A negligible voltage loss at high voltage is also confirmed by the individual electrode potential profiles, where the positive carbon electrode displays a nearly constant evolution of potential. The overall LIC self-discharge is mainly sourced from the NFLF pseudocapacitive electrode. Since the pseudocapacitive faradaic processes are dependent on the short pathways for the Li-ion movement, any contaminant in the electrode acting as a parasitic reaction site could drive minor potential and capacity loss.<sup>[55]</sup> On the other hand, the activated carbon electrode, which is a highly porous electrode, stores charges physically at the EDL, and a constant potential during the open circuit indicates nearly no involvement of parasitic reactions. Furthermore, the LIC was tested via galvanostatic charge/discharge at high current from  $2.5 \text{ mA g}^{-1}$  up to  $100 \text{ mA g}^{-1}$  by the gradual increase of specific current while keeping the cell voltage from 2.2–3.2 V. The GCD curves in Figure S3 further confirm the well-matched mass on both electrodes as the isosceles triangle-shaped profiles are maintained even with an 80-fold increase of the current density. Then, the rate performance is calculated based on these curves where 33.7% of the capacitance is maintained with a larger increase of the current density. Figure S3 and Figure S4a,b show that the symmetry of galvanostatic charge/discharge is maintained throughout the high current applications with very small ohmic loss indicated by the profile of NFLF negative electrode at fully charge state.

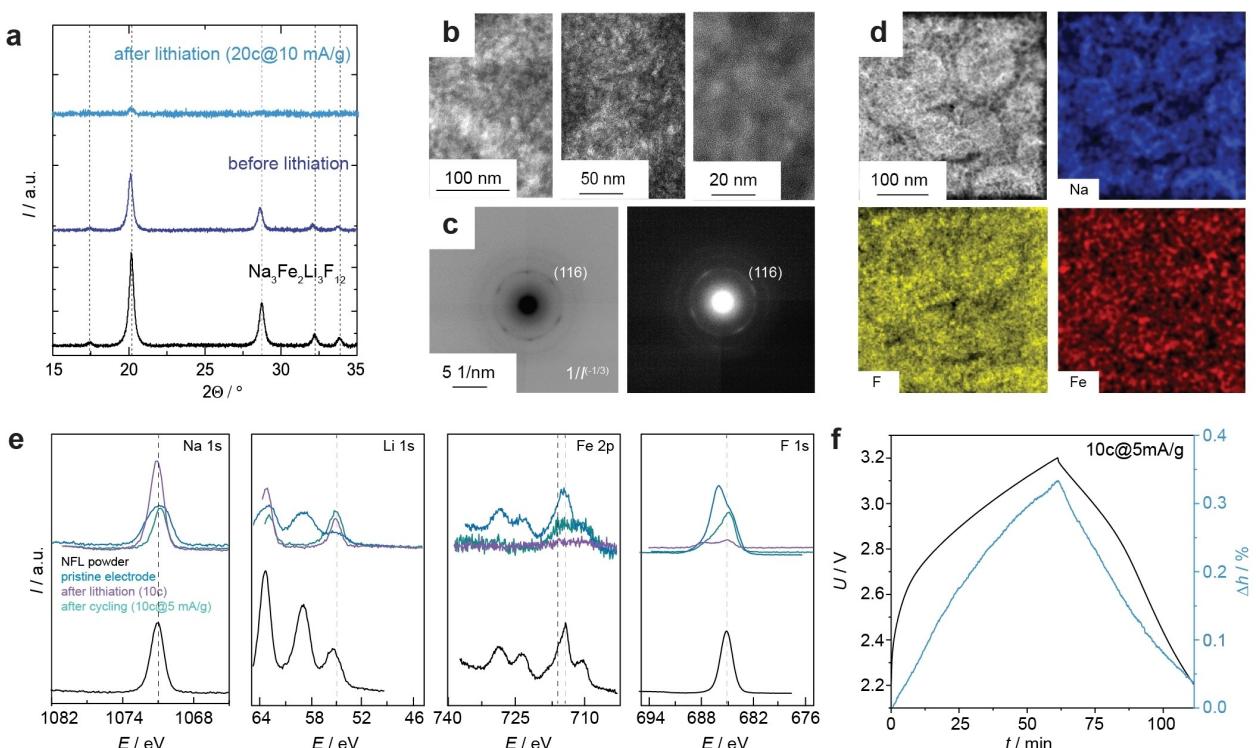

**Figure 3.** Electrochemical performance of lithium-ion capacitors. **a** galvanostatic charge/discharge curve of a hybrid supercapacitor between 2.2–3.2 V with carbon/Na<sub>3</sub>Fe<sub>2</sub>Li<sub>3</sub>F<sub>12</sub> setup, where LiPF<sub>6</sub> (in EC:DMC) served as the electrolyte, and lithium was used as the reference electrode. The current density is expressed per total mass of electrodes. **b** the electrochemical behavior of negative Na<sub>3</sub>Fe<sub>2</sub>Li<sub>3</sub>F<sub>12</sub> electrode during 10000 galvanostatic charge/discharge cycles. **c** capacitance and energy efficiency of Na<sub>3</sub>Fe<sub>2</sub>Li<sub>3</sub>F<sub>12</sub>/carbon hybrid supercapacitor during galvanostatic charge/discharge cycling at 50 mA/g (collected after every 500 cycles). Capacitance is expressed per total mass of NFLF and carbon electrodes including the binder and conductivity enhancer. **d** self-discharge behavior of hybrid cell and electrodes during an open circuit period after charging up to 3.2 V.

Importantly, the two-electrode current-voltage curve in Figure S4c has a square-shape, which indicates the charge storage like a capacitor, which is a cumulative effect of both the capacitive carbon and the pseudocapacitive garnet electrodes. In addition, the presence of a narrow potential window for the positive carbon electrode and an enlarged potential window of the pseudocapacitive negative electrode shows a capacitance disparity between the two electrodes. However, the square-shaped voltage-current curve is evident of the fast charge/discharge of supercapacitor device. Cell voltage vs. log t curve in Figure S4d shows the capacitive discharge mechanism which is related to the faradaic processes of the negative pseudocapacitive electrode and adsorption behavior of activated carbon positive. This behavior is in line with the nearly constant potential window of the positive carbon electrode which does not decay over an open circuit.

The structural alteration of NFLF as observed during electrochemical testing might be related to the insertion of Li-ions into the particle, which causes a volume mismatch between the new phase near the surface and the existing phase in the interior of the particle. The volume mismatch and the associated accumulated stress occurs if the relaxation kinetics is slower (i.e., NFLF has a conductivity of  $\sim 10\text{--}14 \text{ Scm}^{-1}$ , see Figure S5) than the transfer rate, which induces high chemo-mechanical strain potentially causing plastic deformation, mechanical fracturing and even amorphization, as similarly observed for, e.g.,

$\text{LiCoO}_2^{[56]}$  and  $\text{Si}^{[57]}$ . The gradual decrease in particle size resulting in an amorphization of the electrode material is evident from the ex-situ XRD diffraction pattern of the electrode shown in Figure 4a. After cycling only minor indications of crystalline NFLF can be observed as indicated by the decreased intensity of the characteristic reflexes in the XRD pattern of NFLF. Further evidence is given by the TEM micrographs shown in Figure 4b indicating a significant amorphization of the NFLF, while a granular morphology is still visible. Selected area electron diffraction (SAED) data shown in Figure 4c also exhibits a high degree of amorphization and only faint signs of crystallinity can be discerned in some regions. The observed diffractions spots can be assigned to the (116) planes of NFLF with a lattice spacing of  $2.01 \text{ \AA}$ . EDS mapping shown in Figure 4d furthermore reveals an almost homogenous distribution of all constituents (Na, Fe, and F) within the sample. XPS measurements of pristine, lithiated and cycled electrodes in comparison with NFLF powder, points further towards the stability of NFLF (Figure 4e, Supplementary Note S1.5, Figure S6), although some of the characteristic peaks are hardly to observed, due to a potential thick SEI formed during lithiation as well as the amorphization of NFLF which leads to a distribution of bonding energies causing peak broadening with certainty. To exclude that other faradaic reactions, such as conversion reactions are responsible for our observation, we performed operando electrochemical dilatometry (Figure 4f).

**Figure 4.** Post-mortem analysis of lithium-ion hybrid capacitor. **a** X-ray diffraction pattern of  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$  powder as prepared (reference), and in a composite electrode before and after cycling. A significant amorphization of the particles is evident. Just small indications of the main reflexes of  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$  can be detected after cycling. **b** TEM bright field images at different magnifications, showing the granular morphology. **c** Selected area electron diffraction (SAED) giving an only minor indication of crystalline  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$ ; SAED intensity values are transformed by  $I^{(-1/3)}$  for better visibility of the weak reflections. **d** STEM EDS elemental maps show the spatial distribution of all constituents (Na, Fe and F) of cryolithionite. **e** X-ray photoelectron spectra of a pristine electrode as well as after lithiation and after cycling in comprising with NFL powder as a reference. All characteristic peaks can be observed. **f** Electrode potential and thickness during a charge/discharge cycle.

The volume changes over several charge/discharge cycle is below 0.4%, which is less than observed for the activated carbon-based electrodes in EDLCs (from 0.5–2.0%),<sup>[58,59]</sup> and significantly lower than volume changes reported for classical insertion cathodes and in particular conversion-type material,<sup>[60–65]</sup> once again proving the capacitive nature of NFL.

## 4. Conclusions

Cryolithionite is a low cost and efficient anode material with pseudocapacitive charge storage properties and no capacity loss during cycling when implemented in lithium-ion capacitors. The nano-scale iron-derivate of cryolithionite,  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$ , has been synthesized phase pure from abundantly available precursors by precipitation from an aqueous solution without any heat treatment. The electrochemical evaluation indicates that  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$  exhibits a high discharge capacity and the energy is stored via fast pseudocapacitive faradaic reactions which are facilitated by the nanocrystalline transport pathways to the electrode. This material displays a high electrochemical stability window that allows extracting a large cell voltage range between 2.2 V to 3.2 V in a LIC where it is coupled with a positive electrode made from porous carbon for electric double-layer charge storage. The fast charging/discharging of the garnet-based electrode via pseudocapacitive and adsorption storage mechanisms fits well with the fast EDL charging/discharging of nanoporous carbon electrodes. The most important aspect is the high energy efficiency of 93% maintained for 10000 galvanostatic charge/discharge cycles which is superior to the state-of-the-art LICs. Although there are some indications of F-garnet amorphization that mainly occurs during prelithiation step, its impact on the overall supercapacitor is expected to be negligible and is the focus of further studies.

## Supporting Information

Process chart of the synthesis of  $\text{Na}_3\text{Fe}_2\text{Li}_3\text{F}_{12}$ . Further discussion on X-ray diffraction, Mössbauer spectroscopy, Charge/discharge curves of electrodes and hybrid supercapacitors at different current densities, Electrical properties, and XPS spectra.
